**SUMMARY**

Proper regulation of osmotic balance and response to tissue damage is crucial in maintaining intestinal stem cell (ISC) homeostasis. We found that *Drosophila* miR-263a downregulates the expression of epithelial sodium channel (ENaC) subunits in enterocytes (ECs) to maintain osmotic and ISC homeostasis. In the absence of miR-263a, the intraluminal surface of the intestine displays dehydration-like phenotypes, Na⁺ levels are increased in ECs, stress pathways are activated in ECs, and ISCs overproliferate. Furthermore, miR-263a mutants have increased bacterial load and expression of antimicrobial peptides. Strikingly, these phenotypes are reminiscent of the pathophysiology of cystic fibrosis (CF) in which loss-of-function mutations in the chloride channel CF transmembrane conductance regulator can elevate the activity of ENaC, suggesting that *Drosophila* could be used as a model for CF. Finally, we provide evidence that overexpression of miR-183, the human ortholog of miR-263a, can also directly target the expressions of all three subunits of human ENaC.

**INTRODUCTION**

The *Drosophila* intestinal system is an attractive model for studying signaling events that control stem cell homeostasis given its anatomical and functional similarities to human epithelial systems, including the intestine (Jiang and Edgar, 2011). The adult midgut is continuously damaged during feeding as well as by chemicals and pathogens they encounter in the food, and thus needs to be constantly renewed. The renewal process requires tight regulation of the activities of multiple conserved signaling pathways in response to various types of intestinal epithelial injuries. These responses promote both intestinal stem cell (ISC) proliferation and enteroblast (EB) differentiation, expediting the rapid generation of new midgut epithelial cells to replace damaged ones (Biteau and Jasper, 2011; Buchon et al., 2010; Jiang and Edgar, 2011; Jiang et al., 2009; Osman et al., 2012; Zhou et al., 2013).

MicroRNAs (miRNAs) are small non-coding RNAs that post-transcriptionally regulate gene expression. In the past few years, miRNAs have been shown to play an important role in stem cell homeostasis by regulating differentiation and self-renewal (Gangaraju and Lin, 2009; Mathieu and Ruohola-Baker, 2013; Yi and Fuchs, 2012). Here, we found that a well-conserved miRNA, miR-263a, is necessary for maintaining ISC homeostasis. We show that deletion of miR-263a in the adult midgut enterocytes (ECs) activates a stress response that, in turn, activates signaling pathways required for ISC proliferation, resulting in midgut hyperplasia. We identified well-conserved subunits of the epithelial sodium channel (ENaC) as biologically important targets of miR-263a and demonstrate that regulation of these subunits by miR-263a is critical for maintaining proper osmotic homeostasis in the midgut epithelium. Remarkably, many of the phenotypes of miR-263a mutants are reminiscent of the pathophysiology of cystic fibrosis (CF), an autosomal recessive disorder caused by mutations in the gene encoding the chloride channel CF transmembrane conductance regulator (CFTR) (Riordan, 2008). In CF patients, loss-of-function mutations in the CFTR can elevate the activity of ENaC through a mechanism that is not fully understood (Berdiev et al., 2009). ENaC is present at the apical plasma membrane in many epithelial tissues throughout the body to regulate sodium and water reabsorption, ultimately leading to dehydration of the intraluminal surface and reduction in mucus transport (Bhalla and Hallow, 2008). Interestingly, we provide evidence that overexpression of miR-183, the human ortholog of miR-263a, can also directly target all three subunits of human ENaC to regulate its activity. Altogether, our findings describe the role of a miRNA in regulating ENaC levels and suggest that the *Drosophila* intestine could be used as a model for CF.

**RESULTS**

miR-263a Is Required for ISC Homeostasis

To identify miRNAs that regulate ISC homeostasis, we screened for miRNAs that alter the basal number of ISCs in the adult posterior midgut using publicly available miRNA deletion mutants. From the screen, we identified miR-263a as necessary for...
maintaining ISC homeostasis. Using a homozygous viable null allele of miR-263a (miR-263a-)
(Hilgers et al., 2010), we found that miR-263a mutants have an increased number of ISCs, as marked by Delta (DI) expression (Figures 1A and 1B). In addition, many of these ISCs were juxtaposed, suggesting that they undergo symmetric division (Figure 1B). This phenotype is similar to the symmetric division of ISCs seen in neutralized and / integrin (sint-) mutants, where downregulation of DI/Notch signaling leads to frequent ISC duplication, expanding the pool of ISCs (Ohlstein and Spradling, 2007; Okumura et al., 2014).

To determine where in the midgut epithelium miR-263a is expressed, we took advantage of a Ga4 knockin allele of miR-263a (miR-263a-Ga4), in which the miR-263a hairpin sequences are replaced by Ga4 (Hilgers et al., 2010) to drive the expression of a UAS-GFP transgene, thus marking all cells that express miR-263a. GFP expression was restricted to ECs, as evidenced by a lack of GFP expression in either ISCs or EBs, which were marked with esg-LacZ (Figures S1A–S1A’), or in enteroendocrine cells, which were marked with immunostaining of Prospero (Pros) (Figures S1B–S1B’).

To discover whether the increased number of ISCs was due to an increase in proliferation, we stained the midguts using anti-phospho-histone H3 (pH3), a marker for cells undergoing mitosis (Figures 1C and 1D). In miR-263a mutants, the average number of pH3+ cells increased with age while the numbers of pH3+ cells were relatively constant in the control (Figures 1E and S1C). Although miR-263a mutants had higher averages of pH3+ cells in both 7- and 14-day-old guts compared with controls, only the 14-day-old average was statistically different. Overexpression of a miR-263a in a miR-263a mutant background completely suppressed the increase in pH3+ cells (Figure 1E), indicating that the phenotype was due to the absence of functional miR-263a.

Next, we assessed the impact of miR-263a on overall midgut proliferation by generating miR-263a mutant clones using the MARCM (mosaic analysis with a repressible cell marker) approach (Lee and Luo, 2001). Clones of miR-263a mutant cells grew larger than control clones (Figures 1F–1I, S1D, and S1E), consistent with an increase in ISC proliferation. Furthermore, miR-263a mutant clones induced non-cell-autonomous ISC proliferation, as indicated by an increased number of pH3+ and DI+ cells outside the mutant clones (Figures 1F–1I’). These results indicate that loss of miR-263a expression in the ECs can have a non-cell-autonomous effect on ISC homeostasis.

Surprisingly, the miR-263a mutation also had an effect on the overall morphology of the adult midgut. The posterior midguts of the miR-263a mutants were shorter in length and larger in width compared with controls (Figures S1F–S1K). We further observed that shortening and thickening of the midgut was due to multilayering of the epithelium (Figures S1L–S1N). In addition, we observed that multi-layering of epithelial cells was followed by delamination and anoikis of ECs, which is evident by the presence of large lysosomes (Figure S1O).

Identification of Putative miR-263a Targets
To further understand the molecular function of miR-263a in maintaining ISC homeostasis, we searched for miR-263a target genes using TargetScan (Ruby et al., 2007), which predicted 158 targets. Since miR-263a expression is specific to ECs in the adult midgut, we cross-referenced the list of predicted miR-263a target genes with a list of genes that we identified to be specifically expressed in ECs, using the cell-type-specific gene expression profiling technique TADA (Southall et al., 2013) targeted DNA adenine methyltransferase identification using the

Absence of miR-263a Induces Stress and Developmental Signaling Pathways to Promote ISC Hyperproliferation
In the midgut the Jun N-terminal kinase (JNK) pathway is activated in response to EC stress/damage to promote ISC proliferation and differentiation, leading to rapid regeneration of the epithelium to replace damaged ECs (Jiang et al., 2009). To test whether ECs in miR-263a mutants are stressed/damaged, we used a puckered (puc) LacZ reporter line (puc-LacZ) to monitor JNK pathway activity. Using the MARCM approach, we generated miR-263a mutant clones and observed high levels of JNK pathway activation in both mutant clones and neighboring cells (Figures 2A and 2B’). This non-cell-autonomous activation of the JNK pathway is likely caused by ECs that are detaching from the basement membrane due to their larger and more proliferative neighboring miR-263a mutant clones. In a recent study, Notch-defective ISC tumors have been shown to displace surrounding ECs, competing with them for basement membrane space and causing their detachment, extrusion, and apoptosis (Patel et al., 2015). In fact, the multi-layering phenotypes of the miR-263a mutant midgut (Figures S1M and S1N) are very similar to the EC detachment phenomenon observed in the previous study. Furthermore, this non-cell-autonomous activation of the JNK pathway likely stimulates the proliferation of neighboring ISCs (Figures 1I–1I’), which may further expand the expression of puc-LacZ.

Upon activation of the JNK pathway, damaged ECs and surrounding visceral muscle (VM) release ligands that activate JAK/STAT and EGFR/Ras/MAPK signaling pathways to promote ISC proliferation and differentiation (Biteau and Jasper, 2011; Buchon et al., 2010; Jiang and Edgar, 2011; Jiang et al., 2009; Osman et al., 2012; Zhou et al., 2013). Therefore, we examined the expression of these ligands in miR-263a mutant midguts using real-time qPCR. Indeed, we found that expression of the Unpaired cytokines (Upd, Upd2, and Upd3), which activate JAK/STAT signaling, and EGFR ligands, vein (vn), Spitz (Spi), and Keren (Kre), were significantly induced (Figure S2). Next, we examined whether induction of these ligands truly activates JAK/STAT and EGFR/Ras/MAPK signaling. To measure JAK/STAT pathway activity, we used a Stat92E reporter line driving the expression of GFP (10xSTAT-GFP). In control, the expression of 10xSTAT-GFP was restricted to ISCs and EBs (Figure 2C), while large patches of cells expressed the reporter in the miR-263a mutant (Figure 2D). Furthermore, the expression of 10xSTAT-GFP was also present in large misdifferentiated EC-like polypoid cells. To monitor EGFR/Ras/MAPK pathway activity, we examined the levels of phosphorylated ERK (dERK) (Gabay et al., 1997). In control, dERK signals were weakly detected in ISCs and EBs (Figures 2E and 2E’). However, in miR-263a mutants, ectopic dERK signals were mainly observed in large differentiated ECs (Figures 2F and 2F’). Collectively, these results demonstrate that loss of miR-263a in the midgut activates the JNK pathway, which in turn increases the production of both JAK/STAT and EGFR/Ras/MAPK pathway ligands to promote hyperproliferation of ISCs.
RNA polymerase II-DAM fusion protein; D. Doupe and N. Perrimon, personal communication), thus restricting the list to 32 genes. Next, we examined the transcript levels of all 32 genes by qPCR and found that five genes had elevated transcript levels (>2-fold on average) in the miR-263a mutant midguts compared with the control (Table S1). Interestingly, one gene, Nach, had approximately 41-fold higher transcript level in the mutant compared with the control (Table S1 and Figure 3A). Furthermore, we raised an antibody against Nach and found that mutant midguts had significantly more Nach proteins, whereas it was undetectable in the control (Figures 3B and 3C). These striking increases in both the transcript and protein levels prompted us to further investigate whether Nach is a functionally important target of miR-263a in the adult midgut.

**Nach Is a Functional Target of miR-263a in the Adult Posterior Midgut Epithelium**

In Drosophila, Nach (also known as ppk4) is one of 31 family members (termed pickpocket [ppk] genes) that represent ion channels called the Degenerin/epithelial sodium channel (DEG/ENaC) (Zelle et al., 2013). Although the physiological functions of most family members are not known, some have been shown to act as non-voltage-gated sodium channels (Bianchi and Driscoll, 2002; Garty and Palmer, 1997). The Nach 3’ UTR contains three potential miR-263a binding sites (Figure S3A). To determine whether miR-263a regulates the expression of Nach through these binding sites, we generated a luciferase reporter carrying the full-length Nach 3’ UTR. Co-expression of the Nach 3’ UTR luciferase reporter with miR-263a in Drosophila S2R+ cells significantly reduced luciferase activity, while mutating the miR-263a seed sequences, the minimal sequence required for silencing of targets (Brennecke et al., 2005), completely relieved the suppression (Figure 3D). These results suggest that miR-263a can directly regulate the expression of Nach through these binding sites.

(F) Relative transcript levels of human ENaC subunits after overexpression of miR-183 in CFBE41o- cells.
(G) The average number of pH3+ cells in the posterior midguts at 14 days old. Depletion of Nach using two independent RNAi lines and two different Gal4 drivers in the miR-263a mutant background suppressed the increased number of pH3+ cells. The phenotype was also suppressed when other ENaC subunits were depleted in the mutant background. n denotes the number of posterior midguts examined for each genotype. Error bars indicate SEM. **p < 0.05 and ***p < 0.001 (two-tailed t test). See also Figure S3 and Table S1.
miR-183 encodes a second miRNA closely related in sequence to miR-263a called miR-263b. Interestingly, homologous null mutants of miR-263b do not perturb ISC homeostasis (Figure S1C). One possibility is that slight differences in miR-263a and miR-263b seed sequences allow each miRNA to target a different set of genes. In fact, Nach is not a predicted target of miR-263b. Nevertheless, both miR-263a and miR-263b are members of a conserved family of miRNAs that includes mammalian miR-183, miR-96, and miR-182. The high degree of sequence conservation prompted us to ask whether human miR-183, the miRNA most closely related in sequence to miR-263a, has analogous function in regulating the activity of ENaC. In humans, three genes termed sodium channel, non-voltage-gated 1 (SCNN1) alpha, beta, and gamma (SCNN1A, SCNN1B, and SCNN1G, respectively) encode components of the heteromultimeric ENaC (Canessa et al., 1994; Linguere et al., 1993; Waldmann et al., 1995). Based on ortholog prediction (Hu et al., 2011), Nach has two predicted orthologs, SCNN1G and SCNN1B; however, Nach is more closely related to SCNN1G. Strikingly, SCNN1G 3’ UTR contains three potential miR-183 binding sites (Figure S3B), and co-expression of the SCNN1G 3’ UTR luciferase reporter with miR-183 modestly but significantly reduced luciferase activity, whereas mutating the miR-183 seed regions completely relieved the suppression (Figure 3E).

To further investigate the inhibitory potential of miR-183 on SCNN1G, we performed qPCR analyses to measure the endogenous transcript level of SCNN1G after overexpressing miR-183. We used immortalized human CF bronchial epithelial (CFBE410) cells, bearing the most frequent mutation in the CFTR gene (ΔF508), which has increased ENaC activity. Overexpression of miR-183 in CFBE410 cells significantly reduced the endogenous SCNN1G transcript level (Figure 3F), likely through the three miR-183 binding sites we identified (Figure S3B). Strikingly, we also observed significant decreases in the endogenous transcript levels of SCNN1A and SCNN1B (Figure 3F). To investigate whether these are also due to direct interactions with miR-183, we searched for miR-183 binding sites and found multiple sites (Figures S3C and S3D). Co-expression of the 3’ UTR luciferase reporters with miR-183 also modestly but significantly reduced the luciferase activities (Figure S3F). These results demonstrate that overexpression of miR-183 can repress ENaC activity by directly targeting all three ENaC subunits.

To investigate whether misregulation of Nach contributes to the overproliferation of ISCs in miR-263a mutants, we depleted Nach in the miR-263a mutant background. Depletion of Nach by RNAi suppressed the increase in pH3+ cells (Figure 3G). In addition, to address whether Nach activity was required for proliferation of ISCs in general, we examined the consequence of depleting Nach activity on proliferation of ISCs in a gut regeneration model induced by feeding flies with dextran sodium sulfate (DSS) or bleomycin (Jiang et al., 2009; Ren et al., 2010). Knockdown of Nach did not suppress DSS or bleomycin-induced proliferation of ISCs (Figure S3H), indicating that Nach is dispensable for damage-induced ISC proliferation.

In mammals, overexpression of either SCNN1A or SCNN1B subunit alone is sufficient for ENaC activity (Canessa et al., 1994; Mall et al., 2004). Therefore, we asked whether overexpression of Nach alone is sufficient to disrupt ISC homeostasis by increasing ENaC activity. Overexpression of Nach in an otherwise wild-type background failed to increase the number of pH3+ cells (Figure S3I), suggesting that Nach may require additional subunits for full ENaC activity. This result led us to hypothesize that additional ENaC subunits may be misregulated in the miR-263a mutant, and therefore began searching for other ENaC subunits in flies. Out of 12 ppk genes that are predicted orthologs of human SCNN1 genes, only four ppk genes (Nach/ppk4, ppk6, ppk16, and ppk28) are expressed in ECs (Figure S3J) (D. Doupé and N. Perrimon, personal communication), and all have elevated expression in miR-263a mutant midguts (Figures 3A and S3K). Depleting individual ppk genes by RNAi in the miR-263a mutant background suppressed the increase in pH3+ cells (Figure 3G), suggesting that together with Nach they may form a functional ENaC in flies. To determine whether this regulation is direct, we searched and found potential miR-263a binding sites in all three putative fly ENaC subunits (ppk6, ppk16, and ppk28) and performed 3’ UTR luciferase assays. We found that miR-263a was, in addition to Nach, only able to directly regulate the expression of ppk28 (Figures S3E and S3G). Collectively, these results suggest that miR-263a can directly and indirectly regulate the expressions of multiple candidate ENaC subunits.

Sodium Levels Increase in miR-263a Mutant Midgut Epithelium

To examine whether misregulation of ENaC subunits in miR-263a mutants leads to Na+ imbalance in the midgut epithelium, we used an Na+-sensitive fluorescent indicator, Sodium Green, to observe the amount of Na+ in the midgut epithelium. Sodium Green is frequently used to provide spatial and temporal resolution of Na+ concentrations with sufficient selectivity in the presence of physiological concentrations of other monovalent cations (Amorino and Fox, 1995; Minta and Tsien, 1989). Overall, miR-263a mutants displayed a higher amount of intracellular Na+ along the entire length of the midgut as indicated by the increased fluorescence, with three very distinct regions where the increase was most significant (Figures S4A and S4B). Since many of the miR-263a mutant phenotypes we observed are manifested in the posterior region of the midgut, we focused our analyses on this specific region. The posterior midguts of miR-263a mutants had an approximately 4- to 5-fold higher amount of intracellular Na+ compared with control (Figures 4A, 4B, 4C, 4D, 4E, and 4F), suggesting that they are allowing more Na+ across the epithelial membrane. Although disruption of the cell membrane in ECs undergoing delamination and anoikis may allow uptake of more Sodium Green and increase the fluorescent signal in the miR-263a mutants, only a small percentage of the ECs undergo delamination and anoikis; therefore, we do not believe that dying cells are the major contributors of increased Sodium Green fluorescence. Overexpression of miR-263a or depletion of Nach and other ENaC subunits in the miR-263a mutant background completely suppressed the phenotype (Figures 4C–4D, 4F–4G, and 4H). Interestingly, while overexpression of Nach alone failed to increase the number of pH3+ cells, we observed an increase in the amount of Na+ uptake in the midgut epithelium (Figures 4E and 4F). Quantification of Sodium Green fluorescence revealed an approximately 2-fold increase in the intracellular Na+ levels, which is modest compared with the intracellular Na+ of the miR-263a mutants (Figure S4H). This result suggests that...
overexpression of Nach may partially increase ENaC activity, but not enough to stimulate ISC overproliferation. Collectively, these results suggest that increased intracellular Na⁺ in the miR-263a mutant midgut epithelium is due to upregulation of ENaC activity as a result of misregulation of multiple ENaC subunits.

**Reduced PM Thickness and EC Swelling Phenotypes in the miR-263a Mutant Midgut Epithelium**

As an increase in ENaC activity can increase sodium and water reabsorption, ultimately leading to dehydration of the intraluminal surface and reduction in mucus transport (Bhalla and Hallovs, 2008), we examined the midgut lumen and the features of the peritrophic matrix (PM), which plays a role analogous to that of mucous secretions in the vertebrate digestive tract, for signs of dehydration. Electron microscopy of posterior midgut sections revealed that the thickness of the PM in miR-263a mutants was significantly reduced (Figures 5A, 5B, and 5E), and the phenotype was completely suppressed by either depleting Nach or overexpressing miR-263a in the mutant background (Figures 5C–5E). Interestingly, either overexpression of miR-263a or depletion of Nach in the mutant background resulted in thicker PM compared with the control (Figure 5E). Thus, reducing Nach levels by both miR-263a overexpression and Nach RNAi may further reduce sodium and water reabsorption, possibly hydronating the PM and causing it to be thicker.

To investigate whether reduction in PM production was responsible for the reduced PM thickness in miR-263a mutants, we measured the transcript levels of drosocrystallin (dcy), an integral component of the PM (Kuraishi et al., 2011). Strikingly, dcy levels were approximately 16.5-fold higher in the miR-263a mutant midguts compared with the control (Figure S5A). In CF lung disease, excess mucus production and increased transcript levels of MUC5AC and MUC5B, major secreted gel-forming mucins in human airways (Davies et al., 1999; Hovenberg et al., 1996), are common (Hauber et al., 2004; Henderson et al., 2014), which results in mucus with concentrated mucins that collapses onto the underlying epithelium as a first step toward chronic infection and organ disease (Boucher, 2007; Chen et al., 2010; Matsui et al., 1998). Similarly, we found that transcripts of Hemolectin (Hml), a close ortholog of both the human MUC5AC and MUC5B (Hu et al., 2011), are significantly higher in the miR-263a mutant midguts (Figure S5B). Collectively these results suggest that, similar to the CF airway, misregulation of ENaC in the miR-263a mutant midguts results in increased PM production, and that reduced PM thickness is not due to reduced PM production.

In Caenorhabditis elegans, gain-of-function mutations in the orthologs of ENaC (mec-4, mec-10, and deg-1) have been demonstrated to cause vacuolation, cell swelling, and eventual cell lysis (Chalfie and Sulston, 1981; Chalfie and Wolinsky, 1990; Driscoll and Chalfie, 1991; Huang and Chalfie, 1994). Interestingly, we also frequently observed larger ECs in miR-263a mutant midguts, suggesting that they may also be swollen. Staining of the midgut cell membrane, using antibodies against Armadillo (Arm), revealed that miR-263a mutant ECs have a larger surface area compared with wild-type ECs (Figures 5F–5H). In addition, 3D reconstruction of 2D serial sections of ECs revealed that miR-263a mutant ECs have nearly twice the cell volume compared with control ECs (Figure 5I). Next, although we saw a clear increase in the dcy and Hml transcript levels in miR-263a mutant midguts, we further investigated whether genetically disrupting the PM production/thickness was also sufficient to cause EC swelling and hyperproliferation of ISCs. Using a previously characterized loss-of-function allele of dcy (dcy¹) (Kuraishi et al., 2011), we found that dcy mutant ECs were comparable in size with the control ECs, and that dcy mutants did not disrupt ISC homeostasis (data not shown). Collectively these results suggest that EC swelling is not a direct consequence of reduced PM production/thickness but, rather, that increased

expressions of ENaC subunits in the miR-263a mutant midgut epithelium leads to swelling of ECs through increased sodium and water reabsorption.

Increased Bacterial Load in miR-263a

Because structurally compromising the PM is also associated with increased susceptibility to bacterial infections (Kuraishi et al., 2011), we asked whether miR-263a mutants are more susceptible to bacterial infection. Since studies have shown that the Imd pathway regulates antimicrobial peptide production in the gut and plays an important function in the resistance against bacterial infections (Liehl et al., 2006; Nehme et al., 2007; Ryu et al., 2006), we examined the activity of the Imd pathway by measuring the expression of the antimicrobial peptide genes Attacin A (AttA) and Diptericin (Dpt), and the nuclear factor κB-like transcription factor Relish (Rel) in mutant midguts. qPCR analyses revealed that miR-263a mutants showed a stronger induction of all three genes (Figure 6A). Next, to directly visualize antimicrobial peptide expression in the midgut, we used a Drosomycin (Drs) reporter line driving the expression of GFP (Drs-GFP). As expected, miR-263a mutants expressed a higher level of Drs-GFP compared with controls (Figures 6B–6C).

To determine whether increased activation of the Imd pathway is a direct result of increased bacterial accumulation in the miR-263a mutant midgut, we quantified internal bacterial loads by measuring colony-forming units (CFUs). Strikingly, the internal bacterial load in miR-263a mutants was significantly higher compared with the controls (Figure 6D). The observed increase in bacterial load in miR-263a mutants prompted us to investigate whether an inflammatory response to bacteria accumulation was causing ISC overproliferation. To test this hypothesis, we cultured control and miR-263a mutant flies in food containing antibiotics, which eliminated all internal bacteria (Figure 6E). Treatment with antibiotics did not suppress ISC overproliferation in the miR-263a mutants (Figure 6E), indicating that bacterial accumulation is not the primary cause of ISC proliferation.
Next, we investigated whether miR-263a mutants are more susceptible to bacterial infection using *Pseudomonas aeruginosa*, a major pathogen in the CF lung (Ohman and Chakrabarty, 1982; Palmer et al., 2005). Oral infection with *P. aeruginosa* in wild-type flies causes both acute and chronic infection to which the flies ultimately succumb (Mulcahy et al., 2011). After 72 hr of oral infection, miR-263a mutants exhibited a higher susceptibility than wild-type (Figure 6F), indicating that structurally compromised PM leads to increased bacterial infection. Together, our results show that structurally compromised PM in the miR-263a mutants allow for more bacterial infection and have elevated levels of the antimicrobial peptides due to
activation of the Imd pathway. This increased susceptibility to bacterial infection is likely an indirect result from structurally compromised PM, and is not the cause of ISC overproliferation.

miR-263a Mutants Disrupt Intestinal pH Homeostasis

In Drosophila adults the anterior midgut region is neutral in pH, and is followed by an acidic zone (pH < 4) called the copper-cell region. The posterior midgut is mildly alkaline (pH 7–9) and is followed by the hindgut, which is slightly acidic (pH 5) (Dubreuil, 2004; Shanbhag and Tripathi, 2009) (Figure S6A). To assess how structurally compromising the PM influences intestinal physiology, we tested whether intestinal pH homeostasis was perturbed in the miR-263a mutants. The intestinal pH was monitored colorimetrically by feeding animals phenol red as previously described (Shanbhag and Tripathi, 2009). In control midguts only the posterior midgut is dark red, reflecting its high pH (Figure S6A). However, in the miR-263a mutant, almost the entire length of the midgut is alkaline, as revealed by expansion of the dark-red zone (Figure S6B). Alkalization of the mutant midgut is suppressed by overexpressing miR-263a or by knocking down Nach (Figures S6C and S6D). These results indicate that the absence of miR-263a and subsequent increase in Nach activity disrupts intestinal pH homeostasis, which may provide a more favorable environment for bacterial survival.

DISCUSSION

In this study, we describe a mechanism by which a miRNA regulates ENaC to maintain ISC and osmotic homeostasis in the Drosophila midgut epithelium. Specifically, we identified an evolutionarily conserved miRNA, miR-263a, which directly and indirectly regulates the expression of ENaC subunits (Figure 7). Strikingly, the phenotypes of miR-263a mutants are reminiscent of the pathophysiology of CF.

In CF, two different models have been proposed regarding the role of hydration and salt concentration in normal airway defense. Consistent with previous reports that cell swelling can activate the JNK pathway (Berl et al., 1997; Huangfu et al., 2006; Sinning et al., 1997), JNK signaling is activated in miR-263a mutants that have large ECs. In addition, the JAK/STAT and EGFR pathways that regulate ISC proliferation (Biteau and Jasper, 2011; Buchon et al., 2010; Jiang and Edgar, 2011; Jiang et al., 2009; Osman et al., 2012; Zhou et al., 2013) are hyperactivated. Similarly, in CF airway and small intestine epithelia, cells in the airway epithelium and submucosal glands are more proliferative than cells in non-CF airways (Leigh et al., 1995). In addition, all CF mouse models in which CFTR has been deleted, goblet cell hyperplasia was observed in the small intestine (Gallagher and Gottlieb, 2001).

Although the existence of Drosophila CFTR is yet to be determined, given its phenotypic similarities to the pathophysiology of CF, miR-263a mutants may provide a cost-effective and high-throughput animal model for identifying potential therapeutics that can specifically target ENaC in vivo, as the Drosophila gut is amenable to large-scale small-molecule screens (Markstein et al., 2014). In addition, miR-183 might itself be a potential therapeutic agent for regulating ENaC activity in CF, based on our data that overexpression of miR-183 can directly target the expression of all three ENaC subunits in CFBE410 cells (Figure S7). Thus, possibly a combinational therapy for CF using the CFTR potentiator, ivacaftor (also known as Kaldeco [McPhail and Clancy, 2013]), which improves the transport of chloride through the mutated CFTR, together with overexpression of miR-183, could be imagined.

EXPERIMENTAL PROCEDURES

Drosophila Stocks and Genetics

The following Drosophila stocks were used in this study: miR-263a-RNAi, miR-263a-Gal4, and miR-263b-RNAi (Hilgers et al., 2010); btb (Hardiman et al., 2002); UAS-miR-263a (Bejarano et al., 2012); puc-LacZ (puc58) (Martin-Blanco et al., 1998); 10XSTAT-GFP (Bach et al., 2007); Dors-GFP; esg-LacZ (esg5000); Di-LacZ (D08575) (Bloomington Stock Center 11651); Moya-Gal4 (Jiang et al., 2009); hsFlp, Tub-Gal4, UAS-GFP/FM7; Tub-Gal80, FRT40A/CyO (Karpowicz et al., 2010); Nach RNAi (JF02566) (Bloomington Stock Center 27262); Nach RNAi (VDC145921) (Vienna Drosophila Resource Center Stock 45921); ppp6 RNAi (JF01919) (Bloomington Stock 25880); ppp16 RNAi (JF01931) (Bloomington Stock 25890); and ppp28 RNAi (JF02153) (Bloomington Stock 31878). An FRT site (FRT40A) was introduced by recombination onto the chromosome arm carrying the miR-263a-RNAi. All stocks were maintained and crossed at 25°C. For MARCM clones, 2- to 3-day-old adult flies were heat shocked for 1 hr at 37°C to induce clones and kept at 25°C for 14–21 days until dissection. The genotypes used were: (1) hsFlp, Tub-Gal4, UAS-GFP/FM7; Tub-Gal80, FRT40A/CyO; Di-LacZ; (2) hasFlp, Tub-Gal4, UAS-GFP/FM7; Tub-Gal80, FRT40A, miR-263a-Gal4; CyO; Di-LacZ; (3) hsFlp, Tub-Gal4, UAS-GFP/FM7; Tub-Gal80, FRT40A/CyO; puc-LacZ; and (4) hsFlp, Tub-Gal4, UAS-GFP/FM7; Tub-Gal80, FRT40A, miR-263a-Gal4; CyO; puc-LacZ.

Generation of UAS-Nach Transgenic Fly

For construction of UAS-Nach plasmid, Nach genomic fragment was amplified using specific primers (5'-CGAATTCAGGCGCCAGGAGGACG TGAAGC-3'; 5'-GCTCTAGATTCATGTGAATTATGAAAACTGAT-3'). The amplified fragment was digested with EcoRI and XbaI, and was ligated into the linearized pWALIUM10-moe vector. The transgenic fly was established by injecting UAS-Nach plasmid into flies carrying attP docking site, attP2, located on the third chromosome.
Immunostaining of the Midgut

Prior to dissection, flies were fed on 5% sucrose for 3 hr to remove food from the midgut. Female guts were dissected in 1/3 PBS and fixed in 4% paraformaldehyde diluted with 1/3 PBS for 30 min. Samples were washed with 1/3 PBS, and blocked for 30 min in 1/3 PBS, 5% donkey serum, and 0.1% Triton X-100. Samples were incubated overnight at 4°C using the following antibodies: mouse anti-Armadillo (1:50), mouse anti-Delta (1:50), mouse anti-Prospero (1:100) (Developmental Studies Hybridoma Bank), rabbit anti-β-galactosidase (1:1,000; Cappel), mouse anti-β-galactosidase (1:1,000; Promega), rabbit anti-phospho-histone H3 (1:10,000; Millipore), and rabbit anti-P-p44/42 MAPK (dpERK) (1:200; Cell Signaling). Primary antibodies were detected using anti-mouse or anti-rabbit secondary antibodies conjugated to Alexa Fluor 488 and 594 (1:1,000; Invitrogen). Alexa Fluor 488-conjugated phalloidin (1:100; Molecular Probes) was used to stain F-actin. Fluorescent images were acquired with a Leica TCS SP2 AOBS.

Quantification of EC Size

miR-263a mutant clones were generated using the MARCM approach as described above and immunostained using anti-Armadillo to label all cell membranes. The surface area of the miR-263a mutant ECs (GFP+) and their respective nuclei were measured using ImageJ (NIH). The surface area of the wild-type ECs (GFP−), right next to the mutant ECs (GFP+), was used as control. For analysis of the cell volume, serial sections (19–32 sections per individual EC) of individual ECs in the MARCM clones were taken using confocal microscopy. Total cell volume was calculated as follows:

\[
\text{Cell volume (μm}^3) = \text{Total cell surface area (μm}^2) \times \text{Thickness (μm)} / \text{Number of sections}
\]

miR-183 Overexpression in CFBE41o− Cells

Immortalized CFBE41o− cells were obtained from Dr. D. Gruenert (California Pacific Medical Center Research Institute). CFBE41o− cells were grown in MEM (minimum essential medium with Earle’s salt; Life Technologies) supplemented with 10% fetal bovine serum (Life Technologies), 2 mM L-glutamine (Life Technologies), and 1% penicillin/streptomycin (Life Technologies) in 75-cm² flasks and maintained in a 37°C humidified incubator containing 5% CO₂. Cells were routinely grown on flasks coated with an extracellular matrix containing fibronectin/vitrogen/BSA. The miR-183 overexpression experiment was performed on 6-well plates. The day before transfection, each well was seeded with 300,000 cells. Next day, either 1.0 μg of pcDNA3.1-miR-183 or empty pcDNA3.1 (control) plasmid was transfected using Effectene Transfection Reagent (Qiagen). After 72 hr, total RNA was extracted using TRIzol Reagent (Invitrogen). The pcDNA3.1-miR-183 plasmid was constructed by amplying a 399-nt fragment from HEK293 genomic DNA using specific primers (F, 5'-CTAGCTAGCAAGGTCATCTTGGGCTGATG-3'; R, 5'-CCGCTCGAGTCTCTGGGGACACACTGGAC-3'). The amplified fragment was digested with NheI and XhoI, and was ligated into the linearized pcDNA3.1 vector.

Nach Antibody

Nach antibody was generated in rabbit against a peptide containing amino acids 516–535 (CPKANDTHSKEQKSVFIIHKS) and affinity-purified at YenZym Antibodies.

Western Blots

Lysates prepared from dissected adult female midguts were separated by SDS-PAGE, blotted onto nitrocellulose membrane, and subjected to western analysis using antibodies against Nach (1:500) and α-tubulin (1:1,000; Sigma). Blots were subsequently incubated with horseradish peroxidase-conjugated goat secondary antibody (Amersham), and processed for chemiluminescence (Pierce). For quantification of band intensity, the raw images were analyzed using ImageJ (NIH).

Sodium Green Assay

Adult female flies, 14–16 days old, were fed 2 mM cell-permeant Sodium Green Tetraacetate Indicator (Invitrogen) diluted in 5% sucrose for 3–4 hr, and dissected and fixed in 4% paraformaldehyde diluted with 1/3 PBS for 30 min. After a brief wash with 1/3 PBS, samples were mounted, and images were taken immediately using a Leica TCS SP2 AOBS. For quantification of Sodium Green fluorescence, the raw images were analyzed using ImageJ (NIH).
Electron Microscopy
Dissected midguts were fixed overnight in 0.1 M sodium cacodylate buffer (pH 7.4) containing 2.5% glutaraldehyde and 2% paraformaldehyde. The fixed samples were washed three times in distilled water, fixed again with 1% osmium tetroxide and 1.5% potassium ferrocyanide for 1 hr, and washed three times in distilled water. The samples were then washed in 1% maleate buffer and incubated in 1% aqueous uranyl acetate in 1% maleate buffer for 1 hr, followed by two washes in 1% maleate buffer and subsequent dehydration in grades of alcohol. The samples were put in propylene oxide for 1 hr and embedded with a solution of 50% propylene oxide and 50% TAAB Epon over-night. Next day, samples were embedded in fresh TAAB Epon and polymer-ized for 2 days at 60°C. Ultrathin sections (~60 nm) were cut on a Reichert Ultra-cut-S microtome, picked up onto copper grids, and stained with lead citrate. The sections were examined in a JEOL 1200EX transmission electron microscope, and images were recorded with an AMT 2k CCD camera.

Internal Bacterial Load
Age-matched cohorts of ten control and ten miR-263a mutant flies were co-housed in the same vial and were transferred to a new vial every other day. Three vials were used for the analysis. For culture of the internal commensal bacteria, four flies were washed with 70% ethanol for 2 min and rinsed with sterile water twice to remove the external bacteria. Four flies were homoge-nized in 400 μL of MRS medium and serial dilutions were plated on the MRS plates. Plates were incubated at 30°C for 48–72 hr before counting CFUs.

Bacterial Infection Assays
P. aeruginosa PA14 was grown on Luria-Bertani (LB) medium overnight. The following morning, 200 μL of overnight culture was added to 10 mL of LB me-dium and cultured for another 6–8 hr to reach OD600 1.5. Bacteria/sucrose feeding solution was prepared by mixing 1 mL of the bacterial solution with 4 mL of sucrose solution to reach 4% sucrose final concentration. Bacterial infection assay was performed by placing 20 1- to 3-day-old female flies into individual vials containing Kimwipes containing bacteria/sucrose feeding solu-tion at 25°C. Seven vials of each genotype were used. The number of dead flies was recorded every 24 hr. Flies were transferred to new vials with freshly pre-pared bacteria/sucrose solution after 3 days.

Feeding Assays
DSS and bleomycin feeding assays were performed as previously described (Ren et al., 2010). In brief, 11- to 13-day-old female flies were fed either 0.5% DSS or 25 μg/mL of bleomycin (Sigma) dissolved in 5% sucrose solution for 3 days at 25°C. For antibiotics feeding assays, standard laboratory fly food containing 30 μg/mL kanamycin, 100 μg/mL ampicillin, and 34 μg/mL chloram-phenicol was fed to newly eclosed female flies. Flies were transferred to food with fresh antibiotics every 1–2 days. After 16 days, midguts were dissected and examined.

Gut pH Assay
The gut pH was assessed by feeding 14- to 16-day-old female flies 0.2% phenol red dissolved in 5% sucrose solution for 3 hr at 25°C. The colors of the guts were photographed immediately after dissection with Zeiss Axioskop 2 compound microscope.

SUPPLEMENTAL INFORMATION
Supplemental Information includes Supplemental Experimental Procedures, seven figures, and one table and can be found with this article online at http://dx.doi.org/10.1016/j.devcel.2016.11.023.

AUTHOR CONTRIBUTIONS
K.K. and R.-J.H. conceived, designed, and performed the experiments; K.K., R.-J.H., and N.P. analyzed the data and wrote the paper.

ACKNOWLEDGMENTS
We thank Drs. S. Cohen, P. Watnick, and Rolf Bodmer for flies. We thank Dr. D. Gruenert for providing the CFBE410+ cells. We thank the Transgenic RNaI Resource Project, Vienna Drosophila Resource Center, and the Bloomington Drosophila Stock Center for flies, the Developmental Studies Hybridoma Bank for monoclonal antibodies, and the Drosophila RNAi Screening Center (Harvard Medical School) for plate-reader equipment. We thank D. Doupè for sharing unpublished results. We also thank M.-L. Samson, L. Rabinow, S. Mohr, R. Viswanatha, L. Perkins, R. Boucher, and members of the Perrimon laboratory for discussion and critical comments on the manuscript. This work was supported in part by the STARR Foundation (18-A8-030) and by the NIH (grant RO1 GM048947) (N.P.). R.-J.H. is supported by the Jane Coffin Childs Foundation, N.P. is a Howard Hughes Medical Institute investigator.
